

## §9. Turbulence and Transport Characteristics of High $\beta$ H Mode in LHD

Tanaka, K., Michael, C.A., Vyacheslavov, L.N.  
(Budker Institute of Nuclear Physics)

H mode is achieved in LHD at high  $b$  regime ( $\beta > 2\%$ ) [1]. The relation between transport and fluctuation characteristics were studied. Fluctuation, of which wave number region is ITG/TEM region ( $k_{\perp} \rho_i = 0.1 \sim 1$ , here  $k_{\perp}$  is perpendicular wavenumber and  $\rho_i$  is ion Larmor radius) were measured by the two dimensional phase contrast imaging [3]. Figure 1 shows time trace of H mode. Under constant external fueling,  $H\alpha$  signal suddenly dropped at  $t=2.51$  sec and line density started to increase. This is clear indication of the improvement of particle confinement. Energy confinement time ( $\tau_E$ ) was improved transiently at transition timing, however, after transition it became almost same values before transition as shown in Fig.1 (c). Since international stellarator scaling predict positive  $n_e$  dependence, same energy confinement time after transition at higher  $n_e$  indicate degradation of energy confinement.

Figure 2 shows change of  $n_e$ ,  $T_e$  and fluctuation profiles before ( $t=2.3$ sec) and after ( $t=2.7$ sec) H mode transition. As shown in Fig.2 (a) and (d),  $T_e$  did not change before and after transition, while  $n_e$  increased suggesting particle diffusion reduced. Fluctuation shows different behavior depending on its location and propagation direction. As shown in Fig.2 (c) and (f), three different branches are seen. The first one is core ( $\rho < 0.7$ ) ion diamagnetic (i-dia.) component, the second one is edge ( $\rho \sim 1.0$ ) electron diamagnetic (e-dia.) component, the third one is edge ( $\rho \sim 1.2$ ) i-dia. component. The edge i-dia fluctuation power, where fluctuation power is proportional to the square of fluctuation amplitude, did not change after transition although density increased. This indicates that fluctuation level, which was fluctuation amplitude normalized by density, reduced. Previous results showed that the edge i-dia. fluctuation level increased with increase of edge diffusion coefficient [4]. This is consistent that edge i-dia. fluctuation level decreased after transition when edge particle confinement was improved. On the other hands, edge e-dia fluctuation power increased around 10 times (amplitude increased around three times) after transition. Since density increased around factor two, fluctuation level increased factor 1.5. The degradation of energy confinement at high  $\beta$  regime (volume averaged  $\beta > 1\%$ ) and associated increase of low  $k$  ( $k < 0.1 \text{mm}^{-1}$ ) fluctuation level was observed [5]. The  $\beta$  increased from 2% at  $t=2.3$ sec to 2.5% at  $t=2.7$ sec. As described above, energy confinement degraded after transition. The increased e-dia. components might be related to the degradation of the energy confinement.

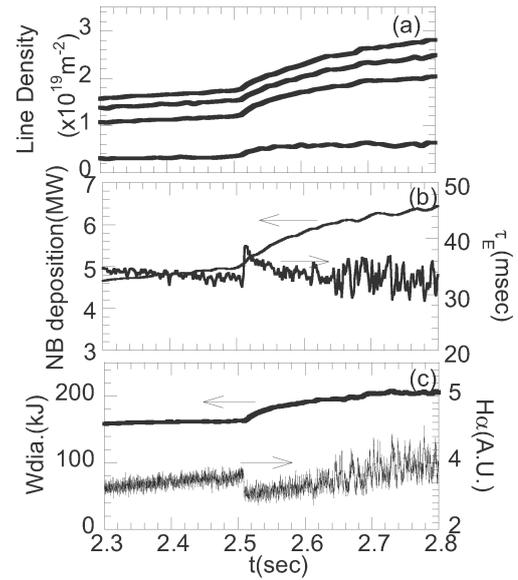

Fig.1 Time trace of (a) line density (from upper, chord position at the equatorial plane is  $\rho = 0.34, 0.58, 0.81, 1.05$ ) (b) Deposition power and  $\tau_E$  and (c) Stored energy and  $H\alpha$ .

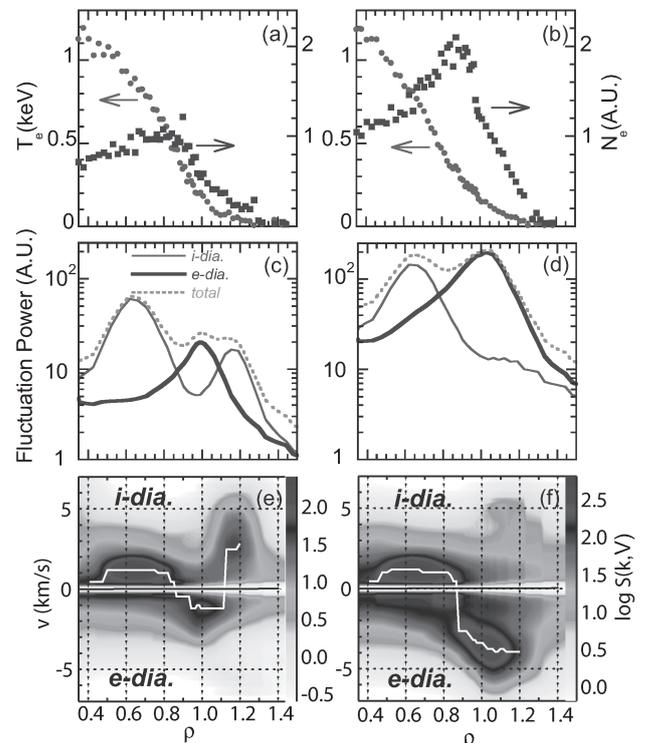

Fig.2 Comparison of profiles before and after transition. (a), (b)  $T_e$  and  $n_e$  profiles (c), (d) spatial profile of fluctuation power spectrum and (e), (f) spatial profile of poloidal phase velocity. (a) is at  $t=2.3$  sec, (c) and (e) are at  $t=2.3 \sim 2.35$ sec. (b), (d) is at  $t=2.7$  sec, (d) and (f) are at  $t=2.7 \sim 2.75$ sec.
