The plasma dynamics and structure are studied by use of the one-dimensional theoretical model for the anomalous transport diffusivities. In this analysis, the high collisional Pfirsch-Schlüter collisional regime is examined and the anomalous particle diffusivity is employed. The reduction of the anomalous particle diffusivity and the steep gradient in the density profile can be obtained. This prediction may be the theoretical explanation for the Internal Diffusion Barrier observed in Super Dense Core plasmas of Large Helical Device.

Keywords: helical toroidal plasmas, turbulent transport, transport barrier, improvement mode, radial electric field, particle confinement

1 Introduction

The turbulence-driven transport and transport barriers are the key issues in fusion research. Main efforts have been focused at the understanding of improved confinement modes (such as the H-mode). Among various improved confinement modes, two main kinds of transport barriers are observed in helical experimental results. At first, the transport barrier because of the radial transition of E_r and the improvement of the electron confinement ('electron internal transport barrier', e-ITB) were observed inside of the transition point for E_r . The transport analysis with the effect of zonal flows could predict an e-ITB in helical plasmas [1]. A comparison with the experimental results was made [2]. As the second kind of transport barriers, an internal diffusion barrier (IDB) is recently observed with the high gradient of the density in a super dense core (SDC) plasma in LHD when a series of pellets is injected [3]. In a core region, the obtained high density and the temperature are around $5 \times 10^{20} \text{m}^{-3}$ and 0.85 keV, respectively. A transport study of a SDC plasma is an urgent and critical issue in helical confinement plasmas. We solve the temporal transport equations for the density, the radial electric field and the temperature to study the dynamics of SDC plasmas in a cylindrical configuration. The additional source profile of the density which corresponds to that in the case of the pellet injection in LHD experiments is studied in the transport equations. The analytical form used here for the neoclassical particle and heat flux related with the helical ripple trapped particles in the high collisional regime is given in ref. [4]. The radial electric filed is assumed to be determined by the ambipolar condition which is constituted with the neoclassical particle flux. The profiles of the density and temperature are determined from the neoclassical and anomalous transport. A transport model for anomalous diffusivities is adapted to describe the turbulent plasma. A dynamics for a self-consistent solution for plasma profiles is examined and the barrier of the particle transport at the inner radial point in the density profile can be reproduced. That can explain a SDC plasma which is accompanied with an IDB in LHD. The profile of the thermal diffusivity is examined when a high-density plasma which corresponds to a SDC plasma is obtained as a calculation result.

2 Model Equations

The model equations used here are shown. dimensional transport model is employed. The cylindrical coordinate is used and r-axis is taken in the radial cylindrical plasma in this article. The region $0 < \rho < 1$ is considered, where a is the minor radius and $\rho = r/a$. The expression for the radial neoclassical flux associated with helical-ripple trapped particles is given in [4] which covers the Pfirsch-Schlüter collisional regime, because the plasma state of a SDC corresponds to the high collisional regime. The total particle flux Γ^t is written as $\Gamma^t = \Gamma^{na} - D_a n'$, where Γ^{na} is the neoclassical flux associated with the helicalripple trapped particles, and the prime denotes the radial derivative. Here, D_a is the turbulent (anomalous) particle diffusivity. The energy flux related with the neoclassical ripple transport, Q_i^{na} is obtained like the neoclassical particle flux. The total heat flux Q_j^t for the species j is written as $Q_i^t = Q_i^{na} - n\chi_a T_i' - 5D_a n' T_j/2$, where χ_a is the anomalous heat diffusivity and Q_i^{na} is the neoclassical contribution from the Pfirsch-Schlüter regime. A theoretical model for the anomalous heat conductivity χ_a is adopted and is explained later. The temporal equation for the density is

$$\frac{\partial n}{\partial t} = -\frac{1}{r} \frac{\partial}{\partial r} (r \Gamma^t) + S_n + S_p, \tag{1}$$

where the term S_n represents the particle source and the parameter S_p is the term to simulate the experimental procedure of the pellet injection. The detail about this term S_p will be explained later. The equation for the electron

temperature is given as

$$\frac{3}{2}\frac{\partial}{\partial t}(nT_e) = -\frac{1}{r}\frac{\partial}{\partial r}(rQ_e^t) - \frac{m_e}{m_i}\frac{n}{\tau_e}(T_e - T_i) + P_{he},(2)$$

where the term τ_e denotes the electron collision time. The term P_{he} represents the absorbed power due to the ECRH heating. The temporal equation for the ion temperature is

$$\frac{3}{2}\frac{\partial}{\partial t}(nT_i) = -\frac{1}{r}\frac{\partial}{\partial r}(rQ_i^t) + \frac{m_e}{m_i}\frac{n}{\tau_e}(T_e - T_i) + P_{hi}.(3)$$

The term P_{hi} represents the absorbed power of ions. The equation for the radial electric field in a nonaxisymmetric system is expressed by the ambipolar condition as

$$\sum_{j} Z_{j} \Gamma_{j}^{na} = 0. \tag{4}$$

In this article, we examine the plasma which consists of the electron and the hydrogen ion. Therefore, the ambipolar condition, Eq. (4) can be rewritten as $\Gamma_i^{na} = \Gamma_a^{na}$. It is well known that the neoclassical transport is dominant when the radial electric field is formed in helical plasmas [5]. The analysis including the temporal equation of E_r [6] which includes the effect of the electric field diffusion is left for the future study. The source profiles are chosen here as follows. The particle source S_n is set to be $S_n = S_0 exp((r-a)/L_0)$, where L_0 is set to be 0.1m. This profile represents the peaking at the plasma edge of the particle source due to the ionization effect. The intensity, S_0 , governs the average density, and is taken as a control parameter to specify the density in this article. The radial profiles of the electron and ion heating terms, P_{he} and P_{hi} , are assumed to be proportional to $\exp(-(r/(0.5a)^2))$ for the sake of the analytic insight.

3 Model for Anomalous Transport Diffusivities and Boundary Conditions

We adopt the model for the turbulent heat diffusivity χ_a based on the theory of the self-sustained turbulence due to the ballooning mode and the interchange mode, both driven by the current diffusivity [7, 8]. The anomalous transport coefficient for the temperatures is given as χ_a = $\chi_0/(1+G\omega_{F_1}^2) \ (\chi_0 = F(s,\alpha)\alpha^{\frac{3}{2}}c^2v_A/(\omega_{pe}^2qR), \text{ where } \omega_{pe}$ is the electron plasma frequency. The factor $F(s, \alpha)$ is the function of the magnetic shear s and the normalized pressure gradient α , defined by s = rq'/q and $\alpha = -q^2R\beta'$. For the ballooning mode turbulence (in the system with a magnetic well), we employ the anomalous thermal conductivity $\chi_{a,BM}$. The details about the coefficients $F(s,\alpha)$, G and the factor ω_{E1} , which stands for the poloidal $E \times B$ rotation frequency, are given in [8] in the ballooning mode turbulence. In the case of the interchange mode turbulence for the system of the magnetic hill [7], we adopt the anomalous thermal conductivity $\chi_{a,IM}$. The details about the coefficients F, G and the factor ω_{E1} in the case of the interchange mode were given in [7]. The greater one of these two diffusivities is adopted as $\chi_a = max(\chi_{a,BM}, \chi_{a,IM})$. The value for the anomalous diffusivities of the particle is set as $D_a = \chi_a$ to examine the radial variation in the profile of the particle diffusivity D_a when the steep radial gradient in the density profile can be obtained as a calculation result.

The equations of density, temperature and electric field (1)-(4) are solved, with the prescribed source profiles, under the appropriate boundary conditions. We fix the boundary condition at the center of the plasma ($\rho=0$) such that $n'=T'_e=T'_i=0$. The boundary conditions at the edge ($\rho=1$), with respect to the density and temperature, are given by specifying the gradient scale lengths. We employ these conditions, -n/n'=0.1m, $-T_e/T'_e=-T_i/T'_i=0.1$ m in this article. The machine parameters which are similar to those of LHD are set to be R=3.6m, a=0.6m, B=3T, $\ell=2$ and m=10. In this case, we set the safety factor and the helical ripple coefficient as $q=1/(0.4+1.2\rho^2)$ and $\epsilon_h=2\sqrt{1-(2/(mq(0))-1}I_2(mr/R))$, respectively. Here, q(0) is the value of the safety factor at $\rho=0$ and I_2 is the second-order modified Bessel function.

4 Dynamical Response after Pellet Injection

Using these parameters and boundary conditions, the onedimensional transport analysis for the LHD-like plasma has been performed and the profiles of n, T_e , T_i and E_r are solved using equations (1), (2), (3) and (4). We adapt a theoretical model for the anomalous transport diffusivities driven by the current diffusivity as a candidate. An example is taken from the plasma which is sustained by the ECRH. At first we obtain self-consistent steady profiles of n, T_e , T_i and E_r for the given source profile. In order to set the line-averaged density to be around $\bar{n} \simeq$ $1 \times 10^{20} \text{m}^{-3}$, the line-averaged temperature of electrons to be around $\bar{T}_e \simeq 0.4 \text{keV}$ and the line-averaged temperature of ions to be around $\bar{T}_i \simeq 0.4 \text{keV}$, the absorbed power of electrons is set to be 1MW and the coefficient S_0 is taken as $7 \times 10^{20} \text{m}^{-3} \text{s}^{-1}$, for the choice of the above mentioned anomalous transport coefficients, where the absorbed power of ions is taken as 0kW. The radial electric field takes the negative value in the entire radial region. Next, we use these obtained profiles of n, T_e , T_i and E_r as an initial condition, i.e., we begin the new calculation from the profile of the density as $\bar{n} \simeq 1 \times 10^{20} \,\mathrm{m}^{-3} \,\mathrm{s}^{-1}$ and the negative E_r in the entire region. In this parameter region examined here, both typical energy and particle confinement times are about 1s. To simulate the experimental procedure of the pellet injection, we add the parameter S_p of the particle source in Eq. (1). This parameter S_p has a distribution as $S_p = S_{p0} exp(-(r/r_p)^2)$ and is set to have a value from the initial time t = 0 to 1ms. We set the half width of the profile S_p as $r_p = 0.2a$. In other words, we set as $S_{p0} = 1 \times 10^{23} \text{m}^{-3} \text{s}^{-1}$ for $0 < t \le 1 ms$ and $S_{p0} = 0 \text{m}^{-3} \text{s}^{-1}$ for t > 1ms. We show the dynamics of the plasma radial profiles n (Fig. 1), T_e (Fig. 2), T_i (Fig. 3) and E_r (Fig. 4) at the times 0ms, 1ms and 10ms. The profiles labelled by

Oms represent the initial conditions used in the calculation in this article (with the dotted lines). As the time goes on, the density increases and the positive electric field appears. In Fig. 1, the rapid change of the gradient in the density profile at t = 10ms can be found at $\rho = \rho_T (\simeq 0.2)$. The parameter ρ_T represents the location of the transition from the positive E_r to the negative E_r at 10ms in Fig. 4. In Fig. 4, we can show the steep gradient of the radial electric field at the transition point ρ_T . (The profile of the radial electric field is determined by the ambipolar radial electric field and the single solution of the radial electric field for the ambipolar condition can be obtained at a radial point.) The gradient of the radial electric field is strong enough to suppress the anomalous transport: $|E'_r| \simeq 1 \times 10^5 \text{Vm}^{-2}$ at $\rho = \rho_T$. Therefore, the improvement near the transition point can be obtained. In Figs. 2 and 3, the temperatures are found to decrease toward the plasma center when the value of the density rapidly increases. After the time 1ms, the density in the core region continues to increase because there is an inward neoclassical transport because the positive gradient of the temperature profiles. If the time passes over the confinement time, the plasma profiles takes initial ones. At t = 10ms, the clear barrier with respect to the particle transport in the density profile can be obtained in Fig. 1.

A profile in the region ρ < 0.5 of the anomalous transport diffusivity is shown in Fig. 5. In the region $\rho < \rho_T$, the reduction of the anomalous particle diffusivity can be found, because the value of the anomalous transport diffusivity is proportional to the square of the safety factor q and the temperatures of electrons and ions decrease toward the plasma center at 10ms. A clear reduction of the anomalous particle diffusivity is found at the transition point $\rho = \rho_T$ due to the strong gradient of E_r compared with the region $\rho > \rho_T$. In the region $\rho < 0.3$ at the time 10ms, the neoclassical particle diffusivity $D_{NEO}(=-\Gamma^{na}/n')$ is found to be much smaller than the absolute value of the effective anomalous particle diffusivity and is $|D_{NEO}| < 0.01 m^2 s^{-1}$ with the dotted line. In the core region, the slightly negative value for the effective neoclassical particle diffusivity D_{NEO} and the particle neoclassical pinch are obtained at the time 10ms. In Fig. 6, the dashed line shows the radial profile of the anomalous particle diffusivity D_a , the solid line shows the radial profile of the sum of neoclassical and anomalous particle diffusivity D_{tot} (= $D_{NEO} + D_a$) at the time 10ms, respectively The clear reduction can be obtained in the sum of the neoclassical and anomalous transport. Therefore, we can obtain the clear barrier with respect to the particle transport in Fig. 1 (n profile at t = 10ms). It is emphasized that the barrier formation starts to occur after the end of the particle fuelling. It takes a few ms for the establishment of a barrier seen in Fig. 5. It is found that the anomalous particle transport has a much more important role on the improvement of the particle confinement in the plasma core region than the neoclassical particle transport in the parameter region examined here. If we set much smaller value for S_{p0} , $S_{p0} = 1 \times 10^{22} m^{-3} s^{-1}$ than that $(S_{p0} = 1 \times 10^{23} m^{-3} s^{-1})$ in this calculation, we can not find the steepening in the density gradient, because the gradient of E_r after the pellet fuelling (1ms) is not strong enough. It is shown that there is a threshold value for S_p to form the barrier with respect to the particle confinement in the density radial profile.

5 Summary and Discussions

We have studied the strong reduction of the particle transport when the dynamics and the radial structure of profiles of the density, the temperatures and the electric field are examined in toroidal helical plasmas. The analysis is performed by use of the one-dimensional transport equations. These transport equations includes the contributions from the neoclassical transport and the anomalous transport driven by the current diffusivity. The neoclassical theory for the particle and heat flux in the the Pfirsch-Schlüter regime is adapted. The radial profile of the electric field is determined by the ambipolar condition. The clear change of the gradient in the density profile and the reduction of the anomalous particle transport in the core region after the particle fuelling, if the value of the particle fuelling (the pellet size in the experiment) exceeds the threshold, can be shown when the temporal evolution of the plasma profiles are examined. This theoretical prediction may explain the Internal Diffusion Barrier (IDB) observed in LHD plasmas. It is predicted that the additional particle source S_p has a threshold value to obtain the reduction of the anomalous transport diffusivity. Furthermore, this threshold value of S_{p0} strongly depends on the shape of the distribution, e.g. the parameter r_p which determines the half-width length of the additional particle source. To study the threshold value of S_{p0} to obtain the clear barrier of the particle transport, the parameter survey of the calculations results is needed. These are left for future studies.

The authors would like to acknowledge Prof. A. Fukuyama for the helpful suggestions related with the numerical methods.
